

Active Bone Marrow Dose Related to Hematological Changes in Whole Body and Partial Body ⁶⁰Co Gamma Radiation Exposures

James B. Keravakis, Ph.D., William Van de Riet, Ph.D., Clifford Born, M.S., Carole Ebling, B.S., Edward Selberstein, M.D., and Eugene Senger, M.D.

INTRODUCTION

The depletion of formed circulating blood elements following exposure to ionizing radiation has been appreciated ^{known for some time} since the turn of the century. Furthermore, it has long been recognized that uniform whole-body exposure is more effective than nonuniform exposure for the production of these hematological changes. Currently, the University of Cincinnati has a program for whole body exposures and for partial body exposures (either upper body, lower body, or complete trunk) of patients for the treatment of cancer. In connection with this program, we have been extremely interested in finding an approach to allow the prediction of the hematological changes to be expected following the uniform and the nonuniform exposures used in our specific study.

A quantitative approach to the evaluation of effects of nonuniform exposure has been proposed by Bond and Robinson (1, 2). They have shown this model to apply to survival prediction of several mammalian species but suggest that it would be expected to apply under other circumstances in which the biological effect scored is related to marrow stem cell survival. The object of the present paper is to extend this model to human survival for the specific uniform and nonuniform exposure procedures used in our program and to test the validity of using this model to predict the ^{radio}peripheral blood levels resulting from the various exposure conditions.

METHODS

The Model

The model proposed by Bond and Robinson is based on the fact that survival in the $LD_{50(30)}$ range depends on the survival ~~of~~^{of} proliferative integrity of a critical number or fraction of the stem cells in the total active bone marrow mass. Mammalian studies suggest that with uniform whole body exposure (same dose to all bone marrow) the number of surviving stem cells in the bone marrow decreases exponentially with dose over a range of exposures that more than spans the $LD_{50(30)}$. Thus, under nonuniform irradiation the unequal distribution of dose to the bone marrow should permit a higher rate of survival than if the same average dose were distributed uniformly.

In their approach, Bond and Robinson assume that sub-units of bone marrow act independently of other sub-units and are subject to the same exponential dose-effect relationship as that for the total marrow. Thus, given the dose to a number of sub-units of bone marrow and the fraction of bone marrow stem cells in that sub-unit, one can determine the relative number of surviving stem cells for each sub-unit. Summing over the entire marrow yields the total relative number of stem cells in the body that would survive the exposure. This value can then be used in estimating the biological effect based on the uniform exposure necessary to produce the same relative stem cell survival. The dose survival curve they propose for human bone marrow stem cells for high energy gamma radiation is shown in Figure 1. The ordinate on the left shows the mortality levels for man corresponding to a given dose of radiation delivered uniformly to all of the marrow. Since

no dose - survival curve ^{was} available for human bone marrow stem cells, the slope of the ^{survival} curve for mouse bone marrow ^{was} ~~has been~~ used. The mouse ^{survival} curve ~~was~~ used by Bond and Robinson is based on the work of McCulloch and Till⁽³⁾ who used the spleen colony Technique and obtained

The Model - continued

a D_0 of 95 rads and an extrapolation number of 1.5 ~~██████████~~ ^{ref. (1, 4, 5, 6)}

As mentioned above, the slope of the mouse curve has been shown to apply fairly well to several mammalian species. Since the shape of the curve at lower doses is not well known for man, the curve shown in Figure 1 has been normalized such that the relative number of stem cells at the LD_{50} for man is 1.0.

In applying this model, one has to know the distribution of bone marrow (assumed to parallel that of stem cells) and the radiation dose distribution throughout the bone marrow. For a detailed distribution of the active bone marrow, the paper by Atkinson was consulted (8). The percentage of total bone marrow distribution times the cellularity factor for the principle bone groups at age 40 were taken from Atkinson's paper. Table I gives ^{a summary of the} ~~the data~~ distribution of active marrow weights in the "Standard Man" at age 40. In the absence of any large scale study of the distribution of active marrow in man, this data is considered to be the best data available at the present. The radiation dose distributions throughout the bone marrow for our specific conditions of uniform and nonuniform exposure were measured in a tissue equivalent phantom as described below.

In a recent paper, Senn and McCulloch (7) have shown by the colony-forming ability in culture technique that the sensitivity of human bone marrow to irradiation ~~is~~ ^{is} of the same order as that predicted on the basis of experiments in mice. The survival curve they obtained for a class of human hemopoietic cells has a D_0 of 137 rads and an extrapolation number of 1.0.

Patient and Phantom Dosimetry

The radiation is delivered by cobalt-60 teletherapy units under the following exposure conditions. The radiation beam is directed horizontally at a wall ³⁴²~~228~~ centimeters away with the patient midline at ~~288~~ centimeters from the source. For whole body exposures, the beam area for the ^{60%}~~50%~~ isodose curve at the patient midline distance is a square approximately 120 centimeters x 120 centimeters ~~120 x 120~~. The patient is placed in the sitting position with legs raised and head tilted slightly forward. Radiation is given by delivering half the specified exposure laterally through one side of the patient; the patient is then turned and the other half exposure delivered laterally through the other side. The variation of air exposure with distance from the source indicated that no correction was required for a possible dose contribution to the patient due to backscatter from the wall.

patient is determined using the percentage depth dose for a 10 sq. centimeter field at 80 cm source to skin distance for the source to skin distance used for the patient. Using the corrected depth dose at patient midline (ionization at the trunk in the plane of the ziphoid) and a factor of 0.957 rads/roentgen for cobalt gamma radiation, the exposure required to give a desired midline absorbed dose in rads is determined.

The validity of this procedure was established in a masonite phantom using thermoluminescence dosimetry.

2) The combined dose ^{to the ziphoid tissue} expected for bilateral ^{exposure} is shown in Figures 3 and 4 for various lateral dimensions. Figure 3 shows

midline exposure there is considerable variation in dose. For a given midline absorbed dose, Table 2 shows dose extremes and the average lateral absorbed dose as a function of the ziphoid over the range of lateral dimensions in our program.

When receiving partial body radiation, the teletherapy unit is used to restrict the beam. The lateral dimension in the patient is again used for calculating the desired midline dose. When the body exposure is delivered bilaterally.

For partial body radiation, the ziphoid was used as the boundary of the body exposure (see Figure 2). From this point on, air exposure rates at the distance of the patient varied from 3 R per minute to 6 R per minute.

A tissue equivalent phantom (Rando) containing a human skeleton and simulated lung cavities was used to experimentally determine the active bone marrow dose under simulated whole body and partial body cobalt-60 exposure conditions. Figure 5 shows the exposure in the Alderson phantom to the cobalt beams to simulate the actual whole body and partial body exposure to humans. Capsules filled with lithium fluoride ^(LiF) were placed in bone cavities as demonstrated by radiographs of each phantom section. The cavities selected were based on locations of active bone marrow spaces as indicated by the work of Atkinson. For each exposure condition, 222 capsules were utilized.

Following exposure, the thermoluminescent dosimeters ^(TLD) were read on an Eberline TLR-5 Reader ^(Eberline Inst. Corp., Santa Fe, New Mexico). The phantom received 300 R midline ^{air} exposure for each exposure condition. This exposure corresponds to an average lateral absorbed dose in the plane of the ziphoid of about 200 rads as calculated by the procedure indicated above.

The majority
most of these capsules were placed in bone cavities with
the remainder being distributed along the midline of the
phantom and in the various body organs.

Clinical Information

The peripheral blood counts of the patients receiving whole body exposure ^{or partial body exposure} in this program were obtained prior to ^{irradiation} exposure and were followed for as long as possible following exposure. The data reported in this paper were obtained from patients shown to have normal blood counts ^(practical) prior to exposure.

RESULTS

a summary of the
~~The~~ integral dose distribution to the bone of the phantom as ^{marrow} obtained from the LIF measurements for 300 R ~~(table)~~ ^{air} midline exposure are shown in Table ~~III~~. Several of the larger bones were arbitrarily divided with several LIF capsules placed in each section. The divisions were made to approximate equal masses of bone and hence an equal weighting factor for the bone marrow within each divided portion. ~~The sum of~~ ^{The} ~~average dose from each section~~ ^{for} ~~was~~ ^{were} then averaged and multiplied by the total ~~grams~~ ^{grams} of active bone marrow in the portion under consideration. The active bone marrow integral doses for upper body, lower body, and complete trunk under simulated human exposure conditions are 48%, 61% and 75%, respectively, of that determined for whole body exposure under the radiation exposure conditions given above. The average midline dose within the primary field area for each exposure condition appears in Table ~~III~~ ^{III}. ~~The~~. The average dose to various organs for each exposure condition is given in Table ~~IV~~ ^{IV}.

Using the radiation dose distribution to the active bone marrow, we proceeded to calculate the weighted stem cell survival for the various exposure conditions. For mortality in the LD₅₀₍₃₀₎ range, the normalized stem cell survival curve as shown in Figure 1 was utilized. An example of the procedure as applied to the pelvic region for whole body and lower body exposure is shown in Table ~~V~~ ^V (~~Table 16~~). The sum over all active bone marrow yields the weighted relative stem cell survival. The calculations were extended to ~~other levels of~~ ^{air} midline exposure ^{other than 300 R} by ~~weighting~~ ^{multiplying} the dose to each bone portion by the ratio of the new exposure level to 300 R. The results of this procedure appear in Figure 6. Thus, for any of the given nonuniform exposures, we can determine from Figure 6 the dose of uniform

The integral absorbed dose for whole body exposure of 300 R divided by the total bone marrow weights yields an marrow weighted average dose of 204 rads to the bone marrow.

RESULTS (continued)

whole body irradiation that would result in the same mortality rate. The corresponding "doses" thus derived for uniform whole body exposures can be thought of as being "dose equivalent," rather than absorbed dose. This is because in the averaging process for nonuniform exposure, each increment of dose was weighted by the amount of bone marrow irradiated at that dose level and by the relative effectiveness of the dose increment to destroy the stem cells. The dose equivalents for 300 R and 600 R midline exposures are shown in Table VI.

In extending this model to the circulating fractions of the peripheral blood elements at the nadir point, the un-normalized mouse ^{bone} marrow stem cell survival curve was utilized ^($D_0 = 95 \text{ rads}$) as ~~well as~~ ^{as well as the survival curve} ~~for human hemopoietic cells ($D_0 = 137 \text{ rads}$)~~. It is assumed in this extension of the model that the nadir circulating fraction for a given blood element is equal to the surviving fraction of marrow stem cells for the given exposure. The model was applied as above and the results appear in Figures 7 and 8.

We tested the validity of this extension of the model by comparing the predicted and measured nadir circulating fractions of white blood cells and platelets for several groups of patients. We grouped the patients by the type of exposure and the midline dose received. Table VII shows the comparison for three groups of patients who received whole body exposures to achieve 100, 150, and 200 rads midline ^{absorbed} dose respectively, and two groups of patients who received lower body exposures to achieve 200 and 300 rads midline ^{absorbed} dose respectively. A small number of patients in our study received trunk and upper body exposure but not in sufficient numbers to group them for an adequate comparison with ^{the proposed} ~~the~~ model.

DISCUSSION

Figure 4 reveals that considerable variation in dose to bone marrow subunits is expected for a given midline^{air} exposure to Cobalt-60 radiation delivered bilaterally. In spite of this, it is interesting to note that the average lateral absorbed dose in the plane of the phantom's ziphoid calculated from the percentage depth dose curve yields a value which is very close to the marrow weighted average dose based on the ~~TL~~^{thermoluminescence dosimetry} measurements and the effective dose based on the stem cell survival model for whole body exposure. Thus, we feel that the calculated average lateral absorbed dose in the plane of the ziphoid provides a means^{of} comparing patients with our phantom studies provided the patient is neither extremely obese nor extremely thin.

The approach to nonuniform exposure proposed by Bond and Robinson is based on an exponential survival curve for bone marrow stem cells. Thus, under nonuniform irradiation the ~~equal distribution of dose to~~^{air} the bone marrow should permit a higher rate of survival than if the same average dose were distributed uniformly. This point was made abundantly clear in our phantom studies. For example, an upper body exposure of 600R would result in a marrow weighted absorbed dose of about 200 rads yet the "dose equivalent" of 600 R upper body exposure is only about ⁹⁵~~100~~ rads.

The Model as proposed by Bond and Robinson assumes that, for a man to survive the hematopoietic crisis, his supply of the critical type (or types) of mature cells during this period (descended from surviving stem cells) must exceed the minimum required for survival. In these terms, the model they propose is based on the assumptions: (a) that the total number of mature cells is proportional to the total number of surviving

DISCUSSION - (Continued)

stem cells, whatever their distribution in the body; and (b) that the requirement for mature cells following any nonuniform exposure is the same as that following the uniform exposure equivalent to it with respect to total ~~stem~~ cell survival. In extending this model to the nadir peripheral blood levels, an additional assumption was made: that the nadir circulating fraction of the given blood element is ~~proportional~~ equal to the surviving fraction of marrow stem cells.

These assumptions as well as the application of the mouse stem cell survival curve to man appear to yield fair agreement between the *proposed* model and the average clinical findings. Because of the wide range in our clinical findings, however, additional clinical data are obviously needed. Also, ^{*more work is needed on 7.1.2*} the specific dose-effect curve for human stem cells ~~is needed~~. If the value for D_0 or extrapolation number for man *in vivo* is markedly different from those used in the calculations, the model as applied to our phantom measurements would have to be altered.

We have a program at the University of Cincinnati College of Medicine for total body exposure and for partial body exposure (either upper ~~half~~ or lower ~~half~~) of patients for treatment of cancer. The radiation is delivered by cobalt-60 teletherapy units under the following exposure conditions. The radiation beam is directed horizontally at a wall 338 centimeters away with the patient midline at 282 centimeters from

SLIDE 1
the source. The beam area for the 50% isodose curve at the patient midline distance is a square approximately 70 centimeters x 70 centimeters (slide). The patient is placed in the sitting position with legs raised and head tilted slightly forward. Radiation is given by delivering half the specified exposure laterally through one side of the patient; the patient is then turned and the other half exposure delivered laterally through the other side. ~~The variation of air exposure with distance from the source indicated that no correction was required for~~

~~a possible dose contribution to the patient due to backscatter from the~~

SLIDE 2
~~wall.~~ Preliminary measurements were made in a masonite phantom using ^{small chambers} and thermoluminescence dosimeters placed on lateral surfaces at the midline of the head, ^{trunk} ~~front~~ and knee portions of the phantom. These results are shown on the next slide. It is seen that if midline doses to the trunk, head and knees are compared, the maximum variation in these doses is about 16%. The exposure to the patient is determined as follows.

Percentage depth dose at different depths for 400 square centimeter field area in a source skin distance of 80 centimeters is corrected for the source skin distance used for the patient. Using the corrected depth dose at patient midline (1/2 lateral dimension of the trunk) and a conversion factor of .97 rads/roentgen for cobalt gamma radiation, the

surface dose and midline air exposure required to give a desired midline absorbed dose in rads is calculated. A direct comparison between calculated and measured (phantom) doses was made for one patient who had the same lateral trunk dimensions as the phantom. ~~SLIDE 3 and good agreement was found.~~ ~~The doses indicated by crosses and the measurements by the straight line and it is seen that there is a good comparison with the calculated doses.~~ The combined dose of the two radiation fields is also given in ~~this figure~~ ^{SLIDE 3}. It shows a good homogeneous dose distribution through the patient. Maximum variation in lateral dose distribution was plus or minus 3% for one patient having a lateral trunk dimension of 36 centimeters. Air exposures rates varied from ⁶3R per minute ~~down~~ to ^{3.5}2R per minute as ⁶⁰Co source decayed.

For the individuals receiving partial body radiation, the teletherapy collimator is used to restrict the beam. The ^{spatial} ~~spatial~~ dose distribution for this latter case is shown in the next slide. ^{SLIDE 4 SLIDE 5} The relative dose distribution for upper body radiation is shown in the next slide; ^{SLIDE 6} that for the lower body in the following slide. ^{SLIDE 7} The phantom measurements were measured with thermoluminescent dosimeters. For partial body radiation, the xiphoid was used as the boundary of the field.

^{start} ~~start~~ ^{we} We are then confronted with some approach to allow comparison between the so-called uniform ^(whole body) and the nonuniform ^(partial body) exposures used in our specific study. Although it is easily seen that a nonuniform exposure to penetrating radiation requires a higher dose of radiation to at least some portion of the body to produce a similar or equal degree of a given effect, ~~than it~~ is necessary with uniform whole body exposure, the full quantitative characterization of dose and dose effect relationships are necessarily more complex for nonuniform than for uniform doses. For uniform whole body exposure, all tissues receive essentially the same dose, and thus the dose delivered to any

tissue is satisfactory in characterizing the dose received by the animal. Absorbed dose at the midline, is commonly used for convenience, with no implication that a particularly sensitive organ or region lies in that location. With nonuniform exposure, however, it has been shown clearly that, for death from the bone marrow syndrome, ^{neither} the entrance dose, the absorbed dose at the midline of the animal, the exit dose, the integral dose nor the average dose will normalize and allow dose effect predictions for the full spectrum of different dose distributions. Thus additional factors must be taken into account and a weighted, dose averaging procedure, must be used to predict dose effect relationships. An approach by Vic Bond and the group at Brookhaven ^{National Laboratory} has provided a basis for dealing with nonuniform exposure. The approach is particularly helpful in dealing with the bone marrow syndrome. In this approach, one has to know ~~the dose distribution and also~~ the distribution of bone marrow ^{and the dose distribution to bone marrow,} (assumed to parallel that of stem cells) ~~and the dose distribution to bone marrow.~~ ^{that better data on the active bone marrow distribution in man is urgently needed.}

^{60Co} We were then interested in obtaining dose distribution data for ^{simulated} human ^{namely} exposures, ^{namely}, whole versus upper half and lower half body exposure

4.

To obtain the dose distribution data the following procedure ~~was~~ used.

The purpose is to determine experimentally ^{the} active bone marrow dose under simulated whole body and partial body cobalt-60 exposure conditions for humans. A tissue equivalent phantom (Rando) containing a human skeleton and simulated lung cavities was used. ^{SLIDE 87} Capsules filled with

^{bone} lithium fluoride were judiciously placed in both cavities as demonstrated by radiographs of each phantom section. The cavities selected were based on locations of active bone marrow spaces as indicated by the work mentioned above by Ellis. ⁸ ~~Next series of slides indicates to some extent the place~~ ^{SLIDE 88}

~~bone marrow distribution~~ ^{SLIDE 89} for standard man is given in the next slide. This is the data of Ellis was

obtained from the original work of Mechanik but corrected for percentage cellularity factors as provided by Custer. These are ^{essentially} corrections for the cranium, mandible, vertebral column, and pelvis by cellularity factor values obtained by Custer for the vertebrae. Further work by Atkinson also allows an assessment of the bone marrow distribution

with age as a parameter. In the absence of any large scale study of the distribution of active marrow in man, the ^{data on this slide are} ~~above~~ ^{available} is considered to be the best data that can be obtained at present.

In terms of being better able to discuss the bone marrow syndrome, it appears

that better data on the active bone marrow distribution in man is urgently needed.

no

Next series of slides indicates placement

of these thermoluminescent capsules in the phantom. The slides include

the following: radiograph of head section; line drawing of the same section with outline of bone structure and placement of capsules; dosimeter placement in the ribs; dosimeter placement in the vertebra; and dosimeter placement in the pelvis and femoral heads and necks. The next series of

slides indicate exposure in Alderson phantom to the cobalt beams to simulate

the actual whole body and upper half and lower half exposure to humans.

The air exposure in all cases is 300 R corresponding to 189 rads at trunk midline. From the average rad dose and the active bone marrow weight, the integral

dose to active bone marrow was calculated. We see in the next slide,

active bone marrow integral doses for lower half body and upper

body under the simulated human exposure conditions are 68.9%

and 37% respectively, of that determined for whole body exposure under

the radiation exposure conditions given above. It has been calculated

that upper half body irradiation results in exposure of 56% of the

active bone marrow of the body whereas lower half body exposure represents

exposure to 44% of the body active marrow. These percentages correspond

very closely to the actual portions of the body irradiated for the

upper and lower exposures. We then proceeded to determine

that for a given nonuniform dose distribution, the dose of uniform

whole body irradiation would result in the same mortality rate,

as determined by using the relative stem cell survival data. The

McCullough

~~of the dose increment to destroy the stem cells.~~ The dose survival curve for bone marrow stem cells is known most accurately for the mouse. A model presented by Bond to handle nonuniform exposure has been shown to apply to the rat and the dog as well as the mouse, using the same curve for stem cells. It was thus assumed by Bond and also assumed in this paper that this curve applies to man. The model also assumes the following: ~~that the number of mature cells is proportional to the total number of surviving stem cells whatever their distribution in the body;~~ that the requirement for mature cells following any nonuniform exposure is the same as that following the uniform exposure equivalent to it with respect to total stem cell survival. It also assumes a moderate degree of nonuniformity-extremes of local dose to any part of the body not exceeding a value of approximately 1000 to 1200 rads. The reason for this is that the higher doses may cause local blood vessel damage to become a significant factor leading to increased requirements for both neutrophils and platelets. In addition, high doses locally to the bowel can produce death in the absence of significant marrow damage.

exposure. Each subunit of bone marrow appears to act independently of the other subunits, as regard to their response to radiation of the stem cells in that subunit. Given the dose to a number of subunits in marrow and percent of bone marrow stem cells in that subunit, one can determine the relative number of surviving stem cells for each subunit using the approach by Bond which is based primarily on survival of stem cells given by ~~Montgomery~~ ^{Y. H. Montgomery} and ~~Montgomery~~ ^{Montgomery} for mice. Summing over the entire marrow ^{fields} the total relative number of stem cells in the body that would survive the exposure. The mortality level to be expected from this stem cell survival can then be obtained from the plot showing relative stem cell survival as a function of a dose. Thus for any given nonuniform dose distribution, a dose of uniform whole body radiation ^{cell} that will result in the same mortality rate can then be determined. For

The corresponding "doses" thus derived for uniform whole body exposures can be thought of as being dose equivalent, rather than absorbed dose. This is because in the averaging process for nonuniform exposure, each increment of dose was weighted by the amount of bone marrow irradiated at that dose level, and by the relative effectiveness of the dose increment to destroy the stem cells.

165R averaging dose

SLIDE 20, 21

Further studies will explore trunk irradiation only, head & extremities only, so that correlated with the phantom

dose measurements and perhaps some measurements in patient, we may be able to for radiation effects to accomplish some rule similar to the pooled rule of 9's for burns. Our interest is to predict some relative degree of injury by knowledge of parts of body exposed. (over) back of page

The dosimetry approach presented here
for "active" bone marrow doses allows
us discuss ~~the~~ some relative degree
of hematopoietic injury for partial
body irradiation relative to whole
body irradiation.
